AVL Trees

See Sections 11.2 and 11.3 of the text.
AVL trees are self-balancing Binary Search Trees. When you either insert or remove a node the tree adjusts its structure so that the height remains a logarithm of the number of nodes. No matter what order we insert the nodes, we can search an AVL in $O(\log(n))$ time.

AVL trees were the first such self-balancing trees. They were invented by Georgy Adelson-Velski and Evgenii Landis 1962.
Definition: An AVL tree is a Binary Search Tree with the additional property that for every node in the tree, the left and right subtrees have height that differ by at most 1. We say that the height of a null tree is -1 and the height of a single node is 0; the height of any other node is 1 more than the max of the heights of its children. Here are some AVL trees:
Here is a tree that is not an AVL tree; the children of the root have heights that differ by 2:
One issue with implementing AVL trees is having access to the height of each node. We change the Node class so it has fields

E data;
int height;
Node left, right;
We also change the `insert()` and `remove()` methods to adjust the height at each node on the path between the root and the modified node. The recursive version of the `insert` method is easy to modify. After we come back from the recursive call we reevaluate the height:
private Node insert(E x, Node t) {
    if (t == null) {
        Node s = new Node(x);
        s.height = 0;
        return s;
    }
    else {
        int comparison = x.compareTo(t.data);
        if (comparison == 0)
            t.data = x;
        else if (comparison < 0)
            t.left = insert(x, t.left);
        else
            t.right = insert(x, t.right);
        t.height = 1 + max(height(t.left), height(t.right));
        return t;
    }
}
This much is easy; the interesting part of AVL trees comes lies in the adjustments we need to do when a tree becomes imbalanced. Consider inserts. We have a balanced tree and insert a node and the tree is then unbalanced. Since inserting can add at most one to the height of a subtree this must mean that we have a node $X$ on the path between the root and the inserted node where the height of one child is 2 more than the height of the other. There are 4 possible cases:

a) The insertion was in the left subtree of the left child of $X$
b) The insertion was in the right subtree of the left child of $X$
c) The insertion was in the left subtree of the right child of $X$
d) The insertion was in the right subtree of the right child of $X$
Consider case (a):

The left child of Node X has height $h+2$, while the right child has height $h$. 
We modify this as follows:
Note that we produce this new tree by just reassigning a few pointers, so it is quick to produce. It is easy to check that this is a BST tree, and it now satisfies the AVL property: the two children of the top node now have height $h+1$. Note that the top node has height $h+2$, which is what it had before the insertion, so no further changes are needed in the tree.
Here is code for this:

```java
Node rotateWithLeftChild( Node X) {
    t = X.left;
    X.left = t.right;
    t.right = X;
    return t;
}
```
Example:
There is a symmetric case for inserting into the right subtree of the right child of $X$: 

Before insertion:

```
  X
 /   \
A     t
     /  \  
    B    C
```

After insertion:

```
  t
 /   \  
X     C
     /  \  
    A    B
```

Height of $X$ and subtrees are indicated as follows:
- Height $h$ for $A$, $B$, and $C$.
- Height $h+1$ for the right subtree of $X$. 

The insertion changes the height of the tree, creating a new path from $X$ to its right child $t$. The height is increased by one in the right subtree but remains $h$ in the left subtree of $X$. 

This is a common case in balancing AVL trees or similar balanced binary search trees.
The code for this is:

```java
Node rotateWithRightChild( Node X) {
    t = X.right;
    X.right = t.left;
    t.left = X;
    return t;
}
```
We started out with 4 cases:

a) Insertion in the left subtree of the left child of X
b) Insertion in the right subtree of the left child of X
c) Insertion in the left subtree of the right child of X
d) Insertion in the right subtree of the right child of X

Our simple rotations have fixed cases (a) and (d). The other cases are a bit more complex and require a double rotation.
Consider this example, where we have just inserted 20. The left child of node 23 has height 3, the right child has height 1.

We first do a rotation from node 21 to node 17, but that doesn't fix the problem; the left child of 23 has height 3, the right child height 1.
We then rotate node 21 to node 23 and this does fix the problem:
In general, if we have a situation like this, where the right child of node $X$ has height $h$ and the left child has height $h+2$, we first rotate $t_2$ to $t_1$: 

![Diagram showing the rotation of nodes](image)
We then rotate node t2 to X:

Now both children of the root have height h+1.
The code for this is simple:
Node doubleRotationWithLeftChild( node X) {
    Node t1 = X.left;
    Node t2 = t1.right;
    X.left = rotateWithRightChild(t1);
    return rotateWithLeftChild(X);
}

Of course there is a symmetric method:
Node doubleRotationWithRightChild( node X) {
    Node t1 = X.right;
    Node t2 = t1.left;
    X.right = rotateWithLeftChild(t1);
    return rotateWithRightChild(X);
}
